ABSTRACT

Three-dimensional seismic reflection data are now being used to understand a range of fundamental geological processes. However, like most geological investigative tools, it is the products of geological processes that are revealed by these data rather than the processes themselves; processes inevitably need to be inferred. We outline how the interpretation of three-dimensional seismic data is undertaken in sedimentary basins and then describe selected examples of recent applications of these data with the objective of showing how sedimentary basin processes can be unraveled from seismic imagery. These examples cover the diverse disciplines of (1) geomorphology and process sedimentology, (2) diagenetic processes, (3) magma intrusion into the upper continental crust, and (4) fluid flow in sedimentary basins.

INTRODUCTION

As a byproduct of the search for hydrocarbons, the earth sciences community has advanced the frontiers of earth science through the development and refinement of the equivalent of the medical world's computed tomography (CAT) scan. Three-dimensional seismic reflection technology enables the geoscientist to image volumes of Earth's subsurface much in the same way CAT scans image the human body. These types of data have long been used in the hydrocarbon industry (e.g., Bally, 1987; Weimer and Davis, 1996; Brown, 1999; Davies et al., 2004) and increasingly in the past decade have been revealing the three-dimensional form of a host of new geological phenomena in sedimentary basins. Three-dimensional seismic reflection profiling is now shedding light on fundamental geologic processes that span a surprisingly wide range of earth science disciplines, from structural geology to geomorphology to fluid migration through strata within sedimentary basins.

Like its medical counterpart, three-dimensional seismology is a form of remote sensing; a means of imaging the interior of a solid object in a noninvasive way. The transmission of seismic energy and the return of energy back to the surface by reflection and refraction allows for some of the fabric and texture of Earth to be imaged, digitally enhanced, and evaluated. The resultant images capture snapshots of the subsurface at a moment in time, and analysis of a series of images facilitates the reconstruction of the geological evolution of the subsurface. The scale of such analysis ranges from whole Earth (e.g., Grand et al., 1997) to the relatively shallow parts of the crust examined in this contribution.

DATA AND INTERPRETATION

Three-dimensional reflection seismology began to be developed in the 1970s. Rather than acquiring parallel seismic line data separated by kilometers, as was the norm with two-dimensional seismic acquisition, acoustic data from multiple closely spaced rectilinear lines were collected (at first every 100 m, then every 50 m, and now commonly every 25–12.5 m), providing regular, grid-like, data point spacing. These data pass through various operations during seismic processing (Yilmaz, 2001) that ultimately aim to increase the signal-to-noise ratio and resolution of the subsurface reflections. The result is a three-dimensional cube of seismic reflections that can be interrogated using a wide range of interpretation software. Three-dimensional seismic coverage in mature hydrocarbon provinces can cover entire sedimentary basins, and global coverage is increasing as acquisition, processing, hardware, and software costs are decreasing. The sheer vertical and lateral extent of data coverage means that tens of meters to basin-scale phenomena can be analyzed.

The interpretation methodology is riddled with buzzwords, many of which are specific to the growing number of software products that can be employed to interpret and visualize these data. Seedpicking, autopicking, voxelbodies, and reflection attributes are a few of the terms that have become part of the seismic interpreter's vocabulary (e.g., Brown, 1999). With specialized software, however, basic interpretation procedures are straightforward. Like any geologic mapping campaign, interpretation usually starts with a phase of reconnaissance. Because the distance between seismic lines is so close (e.g., 12.5 m or 25 m), the data can be viewed as a contiguous earth cube. By panning through tens, hundreds, and thousands of seismic lines over a matter of seconds and minutes, the subsurface can be animated, and the geology “comes alive.” Panning through multiple, closely spaced seismic sections represents the equivalent of viewing an outcrop in a quarry wherein layer upon layer of vertical or horizontal sections are stripped away; the observer witnesses the changes in geology in three-dimensional space. This panning process involves digital manipulation and therefore can be done at any orientation, from vertical to horizontal, and any angle in between. This is informally referred to as “slicing and dicing,” and provides unique insights into the stratigraphic and structural architecture of Earth's upper crust.

Thousands of square kilometers of data can be examined quickly, and key features or areas of interest are readily identified. Within these areas, reflections on individual seismic lines are then traced (so-called “picking”). These
Reflections are low-resolution proxies for individual bedding planes (Vail et al., 1977). Most interpretation software allows the investigator to interpret a small part (spatially) of a specific reflection (these would be called “seeds”) and then instruct the computer to automatically pick the remaining area (so-called “autopicking”). A reflection that covers thousands of square kilometers can be autopicked in as little as a few minutes. Small, complex geologic features with random noise or seismic reflections that are dim or discontinuous represent a greater challenge. They require significant numbers of lines to be examined and more laboriously picked. Because each location within the generated grid (e.g., with an X and Y value) has a unique characteristic (e.g., two-way travel time [Z], horizon dip, seismic amplitude), once the reflection has been picked, the interpreter, again employing specialist software, can quickly calculate what are collectively referred to as “seismic attributes” (Figs. 1 and 2) (see Brown, 1999).

The success of subsequent interpretations depends upon an interpreter’s ability to visualize in three dimensions, recognize geologically significant patterns, and integrate a broad range of geologic disciplines including stratigraphy, geomorphology, structural geology, diagenesis, and magmatism.

**DEPOSITIONAL SYSTEMS ANALYSIS**

The original seismic stratigraphic methodologies outlined in Payton (1977) were developed on two-dimensional seismic cross sections of sedimentary basin fills. No imaging of the planform of the depositional systems and how they stacked was available. Low resolution seismic facies maps, based on qualitative descriptions of seismic reflection amplitude and continuity, as well as reflection architecture (e.g., oblique, sigmoid) and reflection terminations (e.g., toplap, downlap), captured planview distributions of depositional elements. With the advent of three-dimensional seismic data, the analysis of buried landforms became possible; *seismic geomorphology* (Posamentier, 2000) was the logical next step in the seismic analysis of depositional systems. Three-dimensional seismic data, particularly the first second of data (typically the upper 800–1000 m of geology) where the resolution is best, are well suited not only for the static analyses of landscapes and seascapes, in other words the study of “snapshots” of Earth’s surface at a moment in time, but also for the dynamic analyses of these landforms (i.e., how they evolve through time) (e.g., Posamentier, 2001). For example, successive horizontal slices through deposits of a deepwater...
channel-overbank system illustrate the origin and progressive evolution of a crevasse splay from initially poorly organized sediment waves to better organized distributive channels (Fig. 3). Again, this sheds light on processes sedimentologically relevant to the development of deepwater deposition.

As exemplified above, a depositional setting that has benefited particularly from the study of three-dimensional seismic data is the deepwater environment. Deepwater deposits were not well understood in the past for a variety of reasons, including (1) their largely inaccessible location, which made study of these deposits at their deposition sites difficult; (2) the fact that most deepwater settings are not currently areas of active sedimentation; and (3) the fact that even those systems that are active are difficult to study because of the high energy involved in the deepwater sedimentation process. However, over the past 10 years, reservoirs on continental slopes and in deep basinal settings have become increasingly important targets for worldwide exploration as a result of improvements in deepwater drilling technology (e.g., Pettingill, 2001). The infusion of three-dimensional data has literally added a new dimension to the investigation of these deposits (Posamentier and Kolla, 2003). In Figure 4A, for example, a sinuous deepwater channel is shown using a display of the dip azimuth on a reflection marking the top of the channel (Posamentier et al., 2000). The process of thalweg migration within the channel can be recognized using a hori-

Figure 2. Illuminated and perspective view of the surface shown in Figure 1. The elevated aspect of the channel thalweg with its associated levees becomes quite apparent. The inset depicts a cross section through the channel showing that the thalweg is associated with high reflection amplitude, indicative of a higher acoustic impedance relative to the surrounding mud and therefore suggesting the presence of sand. After Posamentier (2003) and Posamentier (2004).

Figure 3. Four time slices through a crevasse splay associated with a Plio-Pleistocene channel in the deep water of the eastern Gulf of Mexico. The splay at Time 1 is disorganized and characterized by subtle transversely oriented sediment waves. Gradually, over Times 2–4, the splay becomes more organized until it is characterized by a well-developed distributive network.

Figure 4. (A) Dip azimuth map on the upper bounding surface of a Pleistocene leveed channel on the deep basin floor in the Makassar Strait, offshore Kalimantan, Indonesia (from Posamentier et al., 2000). Note the extensive sediment waves (corduroy pattern) on either side of the channel. (B) Time slice through this channel illustrating shifted thalweg position through time. Meander loops are observed to migrate in the down-flow direction.
Horizontal slice through a seismic volume (a so-called “time-slice”; see Fig. 4B). Figure 2 shows the presence of slumps on the inner walls of the channel-levee systems, a process that could have an important effect on reservoir properties through the generation of trough-like depressions. The images show that diagenetic fronts may develop nonplanar forms and cause large-scale deformation in sedimentary basins. After Davies (2005). (B) Seismic cube, one face of which intersects the seismic line in A. The front is buried at a depth of 500–700 m, but the overburden has been stripped away (a process known as “sculpting”) to reveal the planform and relief of the opal A to opal CT diagenetic front. It shows that the ridges have a polygonal planform geometry. Green—high; purple—low.

DIAGENETIC PROCESSES

It is not surprising that sedimentary bodies that are tens to hundreds of meters thick and many square kilometers in lateral extent can be studied usefully using three-dimensional seismic reflection profiling. Perhaps less expected is the role that this type of geophysical data could have in the study of diagenetic processes, particularly thermochemical reactions, as one could easily assume that the effects of diagenetic processes are discernable only at pore-scale. Some diagenetic reactions, such as the change from biogenic silica (opal A) to a crystalline form (opal CT), can lead to changes in the porosity and cementation of sediment and therefore have an associated change in acoustic impedance, which means that they can be imaged seismically (Hein et al., 1978). “Seismo-diagenetic” analysis breaks the fundamental seismic stratigraphic rule originally outlined in Payton (1977), because diagenetic reflections are not necessarily time lines. We therefore consider the use of seismic data to understand diagenetic processes to be an exciting, new subdiscipline of seismic stratigraphy.

Like other geologic processes discussed here, the actual processes cannot be witnessed, but the morphology of the fronts can be mapped over areas of $10^2$–$10^3$ km$^2$ of sedimentary basins. This represents a completely different perspective from most conventional diagenetic studies carried out at bed- or pore-scale or limited by two-dimensional seismic data. The three-dimensional shape of opal A to opal CT fronts is starting to yield important clues as to how diagenetic fronts advance through sediments undergoing burial, as well as the controls on this process. In the example shown here (Fig. 5), an industry borehole (214/4-1) has calibrated the seismic data confirming that a bright continuous reflection that cross-cuts stratigraphy is an opal A to opal CT diagenetic front that has developed a polygonal ridge-depression form (Fig. 5A). Because the host sediments are located above a polygonal fault set, they have a preexisting deformational relief that has been adopted by the diagenetic front. Therefore, a starting pattern of polygonal ridges existed at an early stage of front advancement. For reasons that remain uncertain, the diagenetic conversion occurred at the polygonal ridges prior to adjacent sediments, and because it causes porosity loss (Tada, 1991), compaction and overburden subsidence occurred in these areas. This is a new type of differential compaction mechanism that can cause large-scale deformation in sedimentary basins (Davies, 2005). Furthermore, the development of the differential front morphology in itself provides clues as to what processes are potentially involved in front advancement, such as fracturing and mass transport of silica. With the evaluation of additional data and improved geophysical resolution, perhaps other types of diagenetic conversion may be imaged in years to come. Will it be the illite-smectite transition or dolomitization?

MAGMA INTRUSION IN THE UPPER CRUST

The study of igneous intrusions has a research history spanning nearly 200 years. In outcrop, only partial exposure of exhumed sills is common, limiting the totality and consequently the accuracy of the mapping that can be carried out. Insights into how sills propagate and link with each other are therefore limited and rely largely on mechanical models. Two-dimensional seismic data commonly have imaged igneous intrusions and magma bodies (e.g., Joppen and White, 1990; Makovsky and Klemperer, 1999), but the lack of three-dimensional coverage does not allow for evaluation of intrusion processes. Because volcanic continental margins...
are important hydrocarbon provinces, extrusive and intrusive rocks can be imaged using three-dimensional seismic data (Davies et al., 2002; Hansen et al., 2004, Trude, 2004). The true three-dimensional form of dikes and sills can easily be ascertained because igneous rocks have high acoustic contrasts relative to the host sedimentary strata. Sill geometries and seismic attributes such as the amplitude and dip of a reflection from the top of a sill can reveal features that are diagnostic indicators of flow directions (e.g., Thomson and Hutton, 2004). Figure 6 shows a series of finger-like protuberances that are interpreted on the basis of industry borehole calibration in the basin to be part of a dolerite sill that has been intruded into Tertiary-aged silstones and claystones. Because the sill has much higher seismic amplitudes than the surrounding country rock, processing software uses a technique termed “opacity rendering” to render the country rock transparent, revealing the form of the sill. The interpretation of this data set suggests that primary and secondary magma tubes feed secondary and tertiary flow units (Thomson and Hutton, 2004). Although flow direction criteria can be found in outcrops of sills, this example shows that seismic imaging can have an important future role to play in the study of magma intrusion within adjacent sediments and may result in the expulsion of fluids. Both processes are likely to degrade associated reservoir quality.

**FLUID FLOW IN SEDIMENTARY BASINS**

Fluid transport pathways can be detected on some three-dimensional seismic data, at least at a macro scale, because the fluids can change the acoustic properties of the host sediments. Indeed, this geophysical response has historically been a major clue in the hunt for hydrocarbons, as geophysicists have been able to use seismic “bright spots” on two-dimensional seismic data as hydrocarbon indicators (Allen and Peddy, 1993). Understanding fluid flow pathways is another theme that is critical for hydrocarbon exploration and production and has received much attention. Potential fluid flow pathways can be determined by several indirect means using three-dimensional seismic data, including the use of specialist processing. For example, the red coloration in a seismic line from a three-dimensional volume in the North Sea, UK (Fig. 7), indicates the probability of vertical discontinuities representing gas migration pathways, also known as chimneys. The fault on the left of the seismic line shows evidence of being an active gas migration pathway, whereas faults in the center of the line show no evidence of gas migration. The processing software highlights vertical disturbances in the seismic data and assesses the likelihood that they are related to fluid migration pathways. It is critical for hydrocarbon exploration to understand which potential hydrocarbon conduits are active and which are not. From an academic standpoint, this type of analysis has great value in that it can be used to show how sedimentary basins de-gas and how fluids and fluid-sediment mixes enter the atmosphere or hydrosphere. Again, seismic data is not a panacea in this regard, but a tool that can be used in conjunction with other techniques.

**OTHER RESEARCH AVENUES**

There are a plethora of additional avenues of research, which we have not the space to address, to which three-dimensional seismic reflection data sets have made great contributions (Cartwright and Huuse, 2005). Structural geology has benefited just as significantly as the disciplines discussed above. It is not surprising, therefore, that three-dimensional seismic data have allowed extensive study of how faults grow and link, for example (Mansfield and Cartwright, 2001; Walsh et al., 2003). It has also led to the discovery of a new type of fault system, polygonal faults, which were first recognized in three-dimensional seismic data sets from the Tertiary of

**Figure 6.** Plan view of a dolerite sill in which the low amplitude country rock has been made transparent (using an “opacity” technique). The fingers represent magma tubes that have hierarchical organization. Secondary magma tubes are fed from a primary magma tube. These feed secondary flow units that in turn feed the finger-like tertiary flows (after Thomson and Hutton, 2004).

Huuse, M., Duranti, D., Steinsland, N., Guargena, C.G., Pratt, P., Holm, K., Cartwright, J.A., and Hurst, A., 2004, Seismic characteristics of large-scale sandstone intrusions in the Paleogene of the North Sea, UK (e.g., Huse et al., 2004). The subsurface plumbing of giant volcanoes is also now being elucidated (Davies and Stewart, 2005). Three-dimensional seismic reflection data have also been used to examine and further refine our understanding of plate boundaries (Davies et al., 2005). This list of opportunities will no doubt continue to grow in the next decade, particularly given the recent academic funding in the United States for a three-dimensional seismic acquisition vessel.

CONCLUSIONS

Three-dimensional seismic reflection profiling has emerged as a fundamental tool in sedimentary basin analysis. Although the processes cannot be witnessed, their products can have diagnostic geophysical attributes and three-dimensional geometry that provide important clues. The diversity of earth science disciplines benefiting from these data is increasing; however, the costs of such data remain quite prohibitive for academic research. Consequently, because most of these data are acquired by the hydrocarbon industry, academic studies will rely largely on collaboration with this industry. We are truly at the start of the scientific journey; the advances made thus far are dwarfed by future potential.
